Abstract – The objective of this work was to assess the relationship between macrofauna, mineralogy and exchangeable calcium and magnesium in Cerrado Oxisols under pasture. Twelve collection points were chosen in the Distrito Federal and in Formosa municipality, Goiás state, Brazil, representing four soil groups with varied levels of calcium + magnesium and kaolinite/(kaolinite + gibbsite) ratios. Soil macrofauna was collected in triplicate at each collection point, and identified at the level of taxonomic groups. Macrofauna density showed correlation with contents of kaolinite, gibbsite and exchangeable Ca + Mg in the soils. Mineralogy and exchangeable Ca + Mg had significant effects on taxonomic groups and relative density of soil macrofauna. The termites (Isoptera) were more abundant in soils with low exchangeable Ca + Mg; earthworms (Oligochaeta), in soils with high levels of kaolinite; and Hemiptera and Coleoptera larvae were more abundant in gibbsitic soils with higher contents of total carbon.

Index terms: gibbsite, kaolinite, soil fauna, soil fertility, total carbon.

Relações entre macrofauna, mineralogia, cálcio e magnésio trocáveis em Latossolos do Cerrado sob pastagem

Resumo – O objetivo deste trabalho foi avaliar as relações entre a macrofauna, a mineralogia e os teores de cálcio e magnésio, em latossolos do Cerrado sob pastagem. Doze pontos de coleta foram escolhidos no Distrito Federal e no Município de Formosa, GO, e representaram quatro grupos de solo com variados teores de cálcio + magnésio e razões caulinita/(caulinita + gibsita). A macrofauna do solo foi coletada em triplicata, em cada ponto, e identificada quanto ao grupo taxonômico. A densidade da macrofauna foi relacionada aos teores de caulinita, gibsita e Ca + Mg trocáveis. Houve efeito significativo da mineralogia e dos teores de Ca + Mg trocáveis sobre os grupos taxonômicos e sobre a densidade relativa da macrofauna edáfica. Verificou-se maior densidade de Isoptera nos solos com baixos teores de Ca + Mg, de Oligochaeta nos solos cauliniticos, e maior densidade de Hemiptera e larvas de Coleoptera nos solos gibsíticos e com maiores teores de carbono total.

Termos para indexação: gibbsite, caulinita, fauna do solo, fertilidade do solo, carbono total.

Introduction

The Cerrado region, the second largest biome in Brazil, occupies an area of 204 million ha. Native and cultivated pastures extend over an estimated area of 117 million ha, of which 54 million ha are cultivated pastures, according to Sano et al. (2008). The majority of the soils of this region is highly weathered, and characterized by low cation exchange capacity, low base saturation and high aluminum saturation. These characteristics are particularly valid for the Oxisols or “Latossolos”, according to the Brazilian

soil classification (Santos et al., 2006), there soils cover almost half of the region’s total area (Reatto & Martins, 2005). The clay fraction of these Oxisols is predominantly composed of kaolinite, gibbsite, goethite and hematite, in descending order of quantity (Motta et al., 2002).

In tropical soils, notably in the Cerrado biome, macrofauna plays an important role in maintaining ecosystem services (Lavelle et al., 2006), as it is intimately associated with the processes of organic material decomposition and nutrient cycling (Blanchart et al., 2006), and affects the physical, chemical and

biological attributes of the soil (Lavelle & Spain, 2001). Diverse groups of macrofauna, considered “soil engineers” (worms, termites and ants), build structures with diverse physical and chemical characteristics, and are able to influence the availability of nutrients for plants (Decaëns, 2000).

There are still relatively few studies on the macrofauna abundance and diversity in Cerrado pastures. Some authors, such as Benito et al. (2004), Silva et al. (2006) and Marchão (2007) examined transformations in the population of soil macrofauna after the conversion of native Cerrado into agropastoral systems. After these, there were no published studies on the relationship between fertility and macrofauna, nor on the effect of clay fraction mineralogy on soil macrofauna.

This work was based on the premise that soil biodiversity, notably that of invertebrate macrofauna, is intimately linked to chemical and physical attributes and to soil management, and cannot be studied separately. Therefore, we aimed to analyze the relationship between diversity and abundance of macrofauna and mineralogy (kaolinite and gibbsite) and levels of exchangeable Ca + Mg, in Oxisols under pasture in the Cerrado biome.

Materials and Methods

In order to select the study areas, geological and pedological maps of the region were consulted. Based on cartographic analysis, areas with a predominance of Oxisols, were selected. The chosen areas are located in the Distrito Federal, and in the municipality of Formosa, Goiás, Brazil (15°30'S to 16°10'S, and 47°22'W to 48°11'W, respectively), at altitudes ranging from 850 m to 1,200 m a.s.l.

To select the specific points for soil macrofauna sampling, composite soil samples were collected to determine chemical properties. First, exchangeable Ca + Mg was determined using KCl 1 mol L⁻¹ (Claessen, 1997). Then, samples selected for their Ca + Mg contents were analyzed for their kaolinite and gibbsite content by thermogravimetric analysis (ATG), using a TGA-50 Shimadzu equipment (Melo et al., 2001), in order to calculate the kaolinite/(kaolinite + gibbsite) ratios ($R_{K_{Gb}}$). After these procedure, 12 collection points (plots) were chosen for macrofauna sampling, representing four soil groups (GI–GIV) of different characteristics: the soils belonging to GI and GII had low levels of exchangeable Ca + Mg (<1.0 cmol_c kg⁻¹), while soils in GIII and GIV had higher levels (2.1 to 4.0 cmol_c kg⁻¹). In terms of mineralogy, groups I and III had low $R_{K_{Gb}}$ (0.45 to 0.60), while groups II and IV had high $R_{K_{Gb}}$ (0.75 to 0.90) (Table 1, Figure 1). In addition, the total levels of carbon (C) and nitrogen (N) were determined using a Perkin-Elmer CHNS 2400 element analyzer. At the moment of sampling, all plots were occupied by cultivated pastures. The collection points were geo referenced using GPS equipment. The collection point locations and the results of chemical and mineralogical soil analysis for each group are shown in Table 1.

Collection of soil macrofauna took place on the first half of February 2007. At each one of the twelve collection points, three soil monoliths were sampled (Lavelle, 1988). The sampling was done using a 25x25 cm metal quadrat, positioned at random within the central area of the plots, to avoid the effects of vegetation planted along the edges of roads, as well as possible adjacent areas of

Table 1. Levels of carbon (C), nitrogen (N), exchangeable calcium (Ca), magnesium (Mg) and Ca + Mg, kaolinite (k), gibbsite (Gb) and kaolinite/(kaolinite + gibbsite) ratios ($R_{K_{Gb}}$) at the 12 sampling points of Cerrado Oxisols under pasture.

native Cerrado. The soil monoliths were divided into 0–10, 10–20 and 20–30 cm layers to assess the vertical distribution of the macrofauna. Surface litter was also sampled. Separation of macroinvertebrates was performed manually: individuals with a body diameter greater than 2 mm were collected and preserved in flasks containing 70% alcohol, for subsequent counting and classification. Worms were kept in flasks containing 10% formaldehyde solution (diluted in distilled water). All individuals were counted to calculate abundance (individuals m⁻²), and identified to the level of order, at the Embrapa Cerrados laboratory of entomology.

In order to verify whether the distribution of the macrofauna correlated with the soil grouping, Goodman's nonparametric statistical test for contrasts between multinomial proportions, between and within independent populations, was applied (Goodman, 1964, 1965). This is a procedure involving contingency tables, in which the rows feature independent multinomial populations (macrofauna groups), and the columns contain different categories of observed responses (soil groups). Basically, the procedure considers the proportions (rates of occurrence) in relation to the total number of individuals in each taxonomic group and, through contrasts in multinomial proportions, the significances between the soil groups are evaluated, with a level of 5% considered significant.

Results and Discussion

The taxonomic groups (orders), in descending order of their relative density in the samples, were: Isoptera, Hymenoptera, Oligochaeta, Coleoptera (adult and larvae), Diplopoda, Chilopoda, Diptera,

Figure 1. Grouping of sampling points in accordance with levels of exchangeable Ca²⁺ + Mg²⁺ and kaolinite/(kaolinite + gibbsite) ratios (R_{KGb}) in Oxisols under pasture in the Cerrado region.

Hemiptera, Lepidoptera, Homoptera, Symphyla, Araneae, Scorpiones and Pseudoscorpiones (Table 2). Chilopoda, Araneae, Scorpiones and Pseudoscorpiones are predators, which are mainly in the litter layer. Diptera, Gastropoda, Homoptera, Lepidoptera and Symphyla were grouped as “other” due to the low density observed.

The highest abundance of macrofauna was observed in GII (9,263 individuals m⁻²), followed by GI (2,895 individuals m⁻²), GIII (2,150 individuals m⁻²) and GIV (2,075 individuals m⁻²), respectively (Table 2). In all plots, termites (Isoptera) accounted for the greatest number of individuals. The highest relative abundance of Isoptera was found in GII, followed by GI, in soils with low levels of exchangeable Ca + Mg. This can be explained by the fact that these termites are adapted to soils of low fertility and high aluminum saturation (Barros et al., 2002). Benito et al. (2004) also found a greater Isoptera density in soils under degraded pastures than in soils under natural vegetation and pastures managed with fertilizer. The poor litter quality of degraded pastures, as high C/N ratio of plant tissues, as well as the low plant diversity that favors some groups becoming pests can explain the larger Isoptera density, in soils under degraded pastures (Benito et al., 2004; Constantino, 2005).

Coleoptera larvae (98–268 individuals m⁻²) and Hemiptera (260–268 individuals m⁻²) showed the highest abundance in GI and GII (Table 2). This may be related to high C values in these soils (Decaens et al., 1994). However, many factors can affect these insect populations, such as the plant cover species (Santos et al., 2008), the physical impact of cultivation operations, and changes in the nature of carbon sources in the soil-plant system (Benito et al., 2004). Among the Hemiptera, the majority belonged to a species

Table 2. Mean absolute (individuals m⁻²) and relative abundance (%) of macrofauna groups, in the soil groups⁽¹⁾.

Taxonomic group	Soil group			
	GI	GII	GIII	GIV
Isoptera	2,100 (18.45)b	7,031 (61.76)a	1,096 (9.63)c	1,157 (10.16)c
Hymenoptera	249 (8.16)d	1,865 (61.13)a	347 (11.37)c	590 (19.34)b
Coleoptera larvae	98 (20.63)b	52 (10.95)c	268 (56.42)a	57 (12.00)c

commonly known in Brazil as “percevejo-castanho” (*Scaptocoris castanea*), which normally occurs in pastures of *Brachiaria* sp. in the Cerrado region.

The highest densities of earthworms (*Oligochaeta*) were observed in GII and GIV, in soils with high values of $R_{K_{Gb}}$ (Table 2). This could be related to the occurrence of clay types, i.e. kaolinitic and gibbsitic soils in the landscape. According to Reatto et al. (2008), gibbsitic Oxisols – i.e. those of low $R_{K_{Gb}}$ – are mainly located on the well-drained central part of the plateau. In the lower part of the toposequence, in poorly drained position where the water table is closer to the surface, kaolinitic Oxisols or soils of high $R_{K_{Gb}}$ are predominant. According to Auerswald et al. (1996), soil moisture content correlates with earthworm abundance and biomass. Eventually, the kaolinitic Oxisols in the poorly drained lower parts of the toposequence, favoring a higher water retention, are a more suitable habitat for earthworms.

In all soil groups, predators represented less than 1% of the total number of individuals.

In general, it was possible to observe that the levels of exchangeable Ca + Mg had a significant effect on the density of Isoptera, and that variation in levels of kaolinite and gibbsite helped to explain the variation in density of *Oligochaeta*, Coleoptera (larvae) and Hemiptera (Table 2).

These results suggest that the chemical and mineralogical characteristics of soils are considerable variables explaining abundance and distribution of macrofauna in Oxisols under pasture use in Cerrado.

For all the soil groups, the proportion of individuals found in the litter was less than 1%. There were more individuals in the uppermost surface layer (0–10 cm) than in the lower layers, except for GIV, where the highest density of individuals was observed in the 10–20 cm portion (Figure 2), due to a large number of Hymenoptera found in this layer in one of the samples. The concentration of invertebrates in the upper soil layers shows the importance of surface organic material, which is most affected by the addition of organic residues and fertilizers, as observed by Aquino et al. (2008), who verified a positive correlation between density of individuals and organic material in the soil surface. Marchão (2007) also confirmed the greatest density of individuals in the 0–10 cm layer, in soils under pasture in Cerrado.

After Isoptera, the taxonomic groups with high abundance in the 0–10 cm layer were Hymenoptera and Coleoptera (larvae and adult).

The vertical distribution of *Oligochaeta* varied among the soil groups. In GI and GII, representing low levels of Ca + Mg, there was a predominance of

Figure 2. Vertical distribution of macrofauna (Isoptera, all individuals, *Oligochaeta* and Hymenoptera) in the soil groups of Oxisols under pasture, in the Cerrado region.

these individuals in the 0–10 cm layer, which is in accordance with Barros et al. (2002), who found 72% of Oligochaeta in this layer. However, for groups III and IV, from soils containing high levels of Ca + Mg, the vertical distribution of the individuals did not vary among soil layers (Figure 2).

Conclusions

1. Both mineralogy and levels of exchangeable Ca + Mg have a significant effect on the relative and on the absolute abundance of soil macrofauna at the order level.

2. Termite abundance is correlated to soils with low levels of exchangeable Ca + Mg.

3. Earthworm abundance correlates to soils with high levels of kaolinite.

4. Abundances of Hemiptera and Coleoptera larvae correlate to gibbsitic soils with higher contents of total carbon.
