**ABSTRACT:** *In vitro* tests are performed to evaluate the efficacy of antimycotoxins additives (AMAs); nevertheless, such assays show a low correlation with *in vivo* trials, which are also required to determine AMAs' efficacy. In search of an alternative method, the current study investigated the use of an *ex vivo* technique. Six AMAs (AMA1 to AMA6) had their ability to reduce intestinal absorption of aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) evaluated. Jejunal explants were obtained from broilers and subjected to two treatments per AMA in Ussing chambers: T1 (control) - 2.8 mg/L AFB<sub>1</sub>, and T2 - 2.8 mg/L AFB<sub>1</sub> + 0.5% AMA. AMAs were also tested *in vitro* to assess adsorption of AFB<sub>1</sub> in artificial intestinal fluid. In the *ex vivo* studies, AMA1 to AMA6 decreased intestinal absorption of AFB<sub>1</sub> by 67.11%, 73.82%, 80.70%, 85.86%, 86.28% and 82.32%, respectively. As for the *in vitro* results, AMA1 to AMA6 presented an adsorption of 99.72%, 99.37%, 99.67%, 99.53%, 99.04% and 99.15%, respectively. The evaluated *ex vivo* model proved useful in the assessment of AMAs. No correlation was reported between *ex vivo* and *in vitro* findings. Further studies are needed to elucidate the correlation between *ex vivo* and *in vivo* results seeking to reduce animal testing.

**Key words:** intestinal explant, Ussing chamber, broiler, aflatoxin B<sub>1</sub>, mycotoxin binder.

## Uso de modelos *ex vivo* e *in vitro* de intestino de aves para avaliar aditivos antimicotóxicos

**RESUMO:** Testes *in vitro* são realizados para avaliar a eficácia de aditivos antimicotóxicos (AAMs); entretanto, tais experimentos apresentam uma baixa correlação com ensaios *in vivo*, que também são exigidos para determinar a eficácia de AAMs. Em busca de um método alternativo, o presente estudo investigou o uso de uma técnica *ex vivo*. A capacidade de seis AAMs (AAM1 a AAM6) de reduzir a absorção intestinal de aflatoxina B<sub>1</sub> (AFB<sub>1</sub>) foi avaliada. Explantes jejunais foram coletados de frangos de corte e submetidos a dois tratamentos por AAM em câmaras de Ussing: T1 (controle) - 2,8 mg/L AFB<sub>1</sub>, e T2 - 2,8 mg/L AFB<sub>1</sub> + 0,5% AAM. Os AAMs também foram testados *in vitro* para verificar a adsorção de AFB<sub>1</sub> em fluido intestinal artificial. Nos ensaios *ex vivo*, AAM1 ao AAM6 diminuíram a absorção intestinal de AFB<sub>1</sub> em 67,11%, 73,82%, 80,70%, 85,86%, 86,28% e 82,32%, respectivamente. Quanto aos achados *in vitro*, AAM1 ao AAM6 apresentaram adsorção de 99,72%, 99,37%, 99,67%, 99,53%, 99,04% e 99,15%, respectivamente. O modelo *ex vivo* avaliado mostrou-se eficiente na avaliação de AAMs. Não houve correlação entre os resultados *ex vivo* e *in vitro*. Estudos adicionais são necessários para definir a correlação entre achados *ex vivo* e *in vivo* na tentativa de reduzir os testes em animais.

**Palavras-chave:** explante intestinal, câmara de Ussing, frango de corte, aflatoxina B<sub>1</sub>, ligante de micotoxina.

## INTRODUCTION

Antimycotoxins additives (AMAs) are among the multiple approaches used to detoxify aflatoxin-contaminated feedstuffs (OGUZ, 2012). Not all commercially available AMAs have proven efficacy, which should be based on *in vitro* and *in vivo* findings (BRASIL, 2006; MALLMANN et al., 2007).

Most *in vitro* studies employ artificial biological fluids or other models mimicking the animal's gastrointestinal tract (GIT) (AVANTAGGIATO et al., 2003, 2007). Nonetheless, no significant correlation has been reported between *in vitro* and *in vivo* assessments (MALLMANN et al., 2007), and *in vitro/in vivo* extrapolation is a complex issue. Thus, *in vivo* analysis is essential

to prove the efficacy of an AMA. However, animal experimentation has caused great concern regarding welfare and ethical aspects, so different techniques have been associated in order to reduce the number of specimens used (CHELI et al., 2015). In this scenario, the principles of the 3Rs, namely Replacement, Reduction and Refinement, have provided a framework for performing more humane animal research (CLARK, 2019).

*Ex vivo* testing refers to experiments done in animal tissues subjected to external environment, with minimal changes in the natural conditions (BASSO & BRACARENSE, 2013). This technique allows to obtain multiple explants from a single specimen, and has been associated with Ussing chambers (UC) to investigate the effect of mycotoxins, since UC is a valuable tool to measure gut integrity (THOMSON et al., 2019). The impact of mycotoxins on intestinal permeability (AWAD et al., 2007), intestinal occludin expression and direct damage to intestinal villi, as well as products capable of limiting mycotoxins effects (GARCIA et al., 2018; GEREZ et al., 2018), has been demonstrated through this method. YIANNIKOURIS et al. (2013) conducted the first *ex vivo* trial applying UC to evaluate two AMAs, a hydrated sodium calcium aluminosilicate (HSCAS) and a yeast cell wall (YCW), in live intestinal tissue of rats; the latter was more efficient in binding zearalenone (ZEN). Nevertheless, there are no reports in the relevant literature describing the use of this apparatus to evaluate AMAs efficacy using intestinal fragments of birds.

In light of the above, this study tested an *ex vivo* poultry model associated with UC to assess AMAs efficacy. Moreover, the obtained results were compared with *in vitro* findings.

## MATERIALS AND METHODS

### *Broilers and feed*

Feeds free of aflatoxins, fumonisins, ZEN, deoxynivalenol (DON) and T-2 toxin contamination (verified via high performance liquid chromatography tandem mass spectrometry, HPLC-MS/MS) were formulated following nutritional recommendations (COBB-VANTRESS, 2018) and offered to 60 broilers destined for human consumption during the starter (1-20 days) and grower (21-24 days) phases. A feeding design was followed so that twelve birds were sampled daily on the 24th day of life because of the number of UC available to conduct the trials. After cervical dislocation, intestinal samples were collected and immediately tested. As no animal experiment was

performed, the Ethics Committee on Animal Use of the Federal University of Santa Maria (Santa Maria, Brazil) exempted the work from an approval.

### *Mycotoxin and antimycotoxins additives*

A standard aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) was purchased from Sigma Aldrich (St. Louis, MO, EUA), diluted and used at 1.0 and 2.8 mg/L in *in vitro* and *ex vivo* trials, respectively. Such concentrations were used in earlier studies performing *in vitro* and *in vivo* analyses to assess the effect of mycotoxins and additives (JANSEN VAN RENSBURG et al., 2006; KOLAWOLE et al., 2019; MARCHIORO et al., 2013). Three types of AMAs were evaluated, totaling six commercially available products (names have been omitted to ensure confidentiality): 1) AMA1 and AMA2: HSCAS; 2) AMA3, AMA4 and AMA5: HSCAS+YCW association; and 3) AMA6: HSCAS+YCW and seaweed extracts association. The toxin and the AMAs were directly included in the solution inside the UC.

### *In vitro methodology*

An *in vitro* assay was conducted with each AMA before *ex vivo* testing. The product was incubated with AFB<sub>1</sub> at 1.0 mg/L (concentration normally used to assess AMAs *in vitro*) in an artificial intestinal solution at pH 6.0 (THE UNITED STATES PHARMACOPEIA, 1990). Based on recommendation of AMAs' suppliers, an inclusion rate of 0.5% was used (three replicates/AMA); calculation was made according to the volume of the solution in the chamber. The *in vitro* adsorption calculation was estimated from the difference between the fluid with the presence of AMA and the fluid without it using a QTrap 5500 HPLC-MS/MS System (Applied Biosystems, Foster City, CA, USA) equipped with a Turbo Ion Spray electrospray ionisation (ESI) source and a 1290 Series HPLC System (Agilent, Waldbronn, Baden-Württemberg, Germany).

### *Ex vivo methodology*

Four intestinal explants with 2 cm were collected from each broiler, totaling 240 samples (40 samples/AMA). The intestine was opened along the mesenteric border to remove the digesta and washed with cold salty isotonic solution. A pilot study evaluated fragments of duodenum, jejunum and ileum to identify the portion with the best viability (assessed via histopathology after 120-min exposure in the UC). Passage of the toxin across the intestinal explant was also analyzed. Additionally, serosal and seromuscular layers were removed with micro tweezers and scalpels.

Results indicated the jejunum with all its layers as the most suitable portion to perform the experiment.

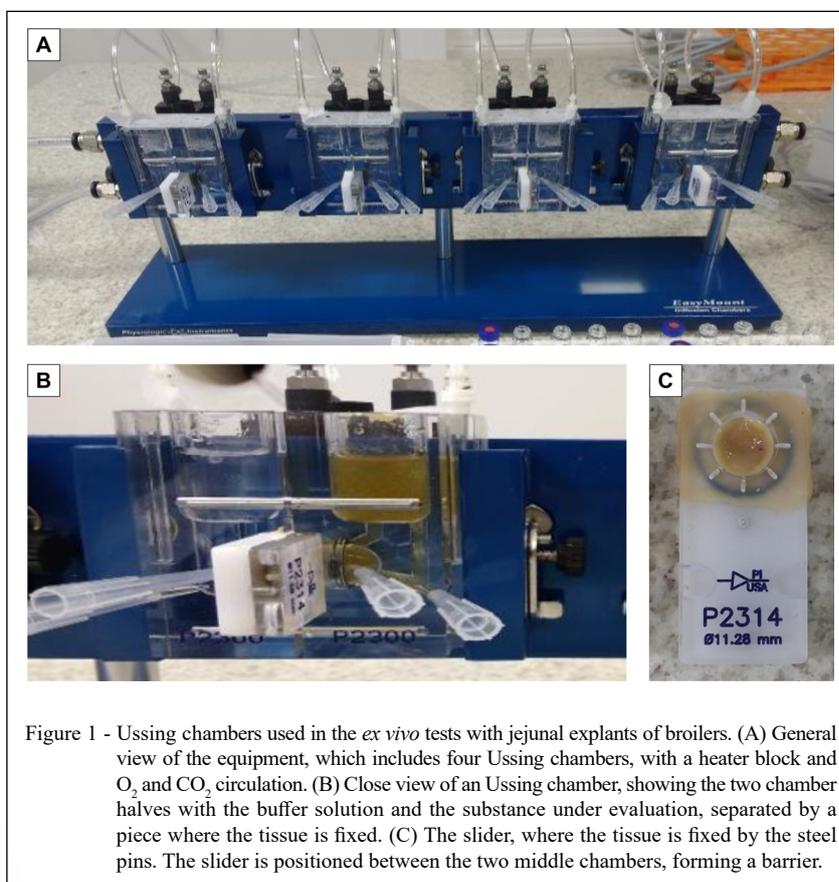

Four pairs of UC (Easy Mount Ussing Chambers, Physiologic Instruments, San Diego, CA, USA) were used. Each chamber half was connected to one vessel containing the same volume of the buffer solution with equal mineral composition. Both vessels were bubbled with a blend of 95% O<sub>2</sub> and 5% CO<sub>2</sub>, which maintained tissue oxygenation and also worked as a supporting gas for the recirculation of the solution in each chamber. The vessels were kept at 37 °C through warm water circulation in the coating around.

The intestinal segment was fixed on the slider between the apical and basolateral sides of the UC. Total area of intestinal contact with the mycotoxin-enriched solution, which corresponds to the free area where the explant is fixed, was 1.0 cm<sup>2</sup> (Figure 1). The explants were subjected to two treatments per AMA (two replicates/treatment) in a block design: T1 (control) - 2.8 mg/L of AFB<sub>1</sub>; and T2 - 2.8 mg/L of AFB<sub>1</sub> + 0.5% AMA. *In vivo* testing with AMAs routinely use AFB<sub>1</sub> at 2.8 mg/kg, hence

the choice to replicate it in the *ex vivo* trials. The jejunal explant was subjected to the UC process for 120 min; a previously incubated solution with AFB<sub>1</sub> and the AMA was included in two UC; in the other two chambers, only AFB<sub>1</sub> was added. The AMAs were incubated with AFB<sub>1</sub> for 30 min prior to testing. The amount of AFB<sub>1</sub> absorbed by the intestinal fragment was measured by HPLC-MS/MS; thus, it was possible to verify the intestinal capacity to absorb the mycotoxin either in the presence of an AMA or not. The following buffer solution (in mmol/L) was used for all the washings and incubations: NaCl - 128, KCl - 4.7, CaCl<sub>2</sub> - 2.5, KH<sub>2</sub>PO<sub>4</sub> - 1.2, MgSO<sub>4</sub> - 2.6, NaHCO<sub>3</sub> - 2.0 and D-glucose - 5.0; pH was maintained at 6.8.

#### Mycotoxin extraction

Immediately after the UC procedure, the explant was placed in a 15 ml Falcon tube with 4 ml of a AFB<sub>1</sub> extraction solution (acetonitrile:water 84:16 v/v) for 1 h. Subsequently, it was macerated to increase contact surface with the solution to ensure complete extraction of the mycotoxin. The macerated

tissue remained in contact with the solution for 1 h, then it was removed and discarded. The tube was centrifuged (10 min, 2,058 x g), then the supernatant was collected and transferred to a 2 ml Eppendorf tube which was also spun (10 min, 20,854 x g, 4 °C). The supernatant was transferred to another 2 ml Eppendorf tube and this content constituted the sample which was diluted and injected into the HPLC-MS/MS system to determine the concentration of the mycotoxin.

#### *Performance parameters in HPLC-MS/MS analysis*

Selectivity was obtained through the addition of potentially interfering factors, both in blank and enriched samples. Linearity was obtained by developing a calibration curve consisting of seven concentration levels: 1, 2, 5, 10, 25, 50 and 100 µg/L; each level had a specific solution prepared in triplicate. Instrumental readings were randomly performed. Linearity was observed by the graphic of the assays results, depending on the concentration of the analyte, and was verified based on the linear regression equation, which was determined by the least squares method.

The matrix effect was evaluated by establishing two calibration curves with seven levels each, as follows: a) calibration curve of the analyte in solution: formulated from pure analyte calibration standards in the solvent; and b) calibration curve of the blank matrix extract fortified with pure analyte calibration standards.

#### *Statistical analysis*

The number of blocks was set according to the test power criterion, with the aid of the software Gpower 3.1.5<sup>o</sup>, using the means and standard deviations obtained in the pilot experiment. A test power of 0.99 was considered for the experimental design calculations. Statistical analyses were conducted using the software Statgraphics Centurion XV (Manugistics Inc., Rockville, USA). Data were subjected to ANOVA using the F Test at 5%. Pearson's correlation was performed between the results obtained in the *ex vivo* and *in vitro* tests. Mean differences in the percentage of reduction in AFB<sub>1</sub> absorption among the AMAs were separated using Tukey's HSD test.

## RESULTS

#### *In vitro and ex vivo analyses*

This study originally aimed to measure AFB<sub>1</sub> passage from the mucosal to the serosal side of

the intestine, that is, from the apical to the basolateral side of the chamber, thus verifying the passage across the intestinal explant in the presence or absence of an AMA. Initial testing subjected an entire intestinal segment to the equipment; however, no significant AFB<sub>1</sub> passage was observed. Afterwards, the seromuscular layer was removed and the explant was resubjected to AFB<sub>1</sub>; stripping was expected to allow the toxin to pass to the basolateral side, since it isolates the tissue from the outside, but passage through the serosal layer was not significant (0.1 to 0.5%).

The next step was to evaluate the concentration of AFB<sub>1</sub> retained in the intestinal explant. Exposure to AFB<sub>1</sub> in the presence or not of an AMA was then performed after having consolidated the technique in the UC with verification of intestinal absorption at different times (Figure 2).

The AMAs were able to bind AFB<sub>1</sub> and prevent its absorption by the intestinal epithelium. There was a lower concentration of the toxin in the intestinal explant in the presence of all AMAs in comparison to the explant exposed to AFB<sub>1</sub> alone ( $P < 0.0001$ ). AMA1 to AMA6 reduced the intestinal absorption of AFB<sub>1</sub> by 67.11%, 73.82%, 80.70%, 85.86%, 86.28% and 82.32%, respectively ( $P < 0.0001$ ); there was a difference between additives in the ability to reduce intestinal absorption of AFB<sub>1</sub> ( $P < 0.0001$ ). *In vitro* data demonstrated an absorption ability of 99.72%, 99.37%, 99.67%, 99.53%, 99.04% and 99.15%, for AMA1 to AMA6, respectively; no significant difference was seen between the AMAs ( $P > 0.05$ ). No correlation (Pearson's correlation,  $P > 0.05$ ) was found between *ex vivo* and *in vitro* findings; so, even though the AMAs presented an adsorption above 99% in the *in vitro* trials, a different pattern was observed in the *ex vivo* assays (Table 1).

#### *Performance of HPLC-MS/MS analysis*

The sample matrix may contain elements which interfere in the measuring performance and may increase/decrease the result. In this study, selectivity was verified by comparing the signs coming from the reading of the processed sample and the analyte of interest. There was no statistically significant difference regarding the impact of the matrix on AFB<sub>1</sub> recovery ( $P > 0.05$ ). The *r* value for AFB<sub>1</sub> was 0.9971 (Table 2).

Linearity evaluation was performed by the visual inspection of the linear regression chart of the calibration curves with and without matrix. A linear correlation coefficient ( $R^2$ ) over 0.99 was considered as ideal. The regression equation used to determinate the line was  $y = ax + b$  (Figure 3).

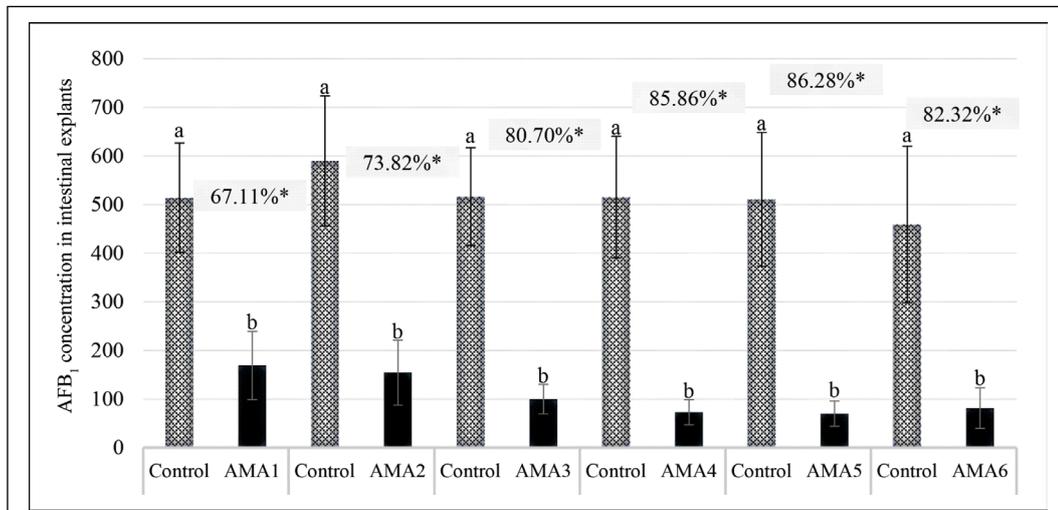

Figure 2 - Aflatoxin B<sub>1</sub> concentration in jejunal explants of broilers in the presence or absence of antimycotoxins additives. AFB<sub>1</sub>: aflatoxin B<sub>1</sub> (µg/kg); AMA1-6: antimycotoxins additives 1 to 6; a-b: means with different letters in the same trial indicate significant difference (F test; P < 0.0001); \*reduction in AFB<sub>1</sub> intestinal absorption in the presence of each AMA.

## DISCUSSION

These findings are in line with those disclosed by YIANNIKOURIS et al. (2013), who used UC mounted with intestinal segments of rats and subjected them to ZEN challenge. The authors reported that the mycotoxin concentration in the tissue was almost the same as that in the chamber, indicating that ZEN concentration gradient was maintained from the basolateral side into the tissue. Nevertheless, passage of ZEN to the serosal side was

restricted (0.4%). The researchers suggested that such behavior could be associated with the lipophilic properties of ZEN, which may lead to an interaction with the lipidic membranes of the intestinal epithelium and cause its encapsulation.

Another study also reported no significant toxin passage to the serosal side of jejunum when assessing DON transport across swine intestines (HALAWA et al., 2013). Pigs received feed containing DON (0, 4 or 8 ppm) and were slaughtered to obtain explants to be mounted on UC; DON (4 or

8 ppm) was introduced to the mucosal side, then the flux rate was evaluated in the specimens that had or not received the contaminated feed. There was a low flux rate in mucosal-to-serosal direction, but the DON-fed animals showed greater permeation due to the damage the toxin had caused *in vivo*. The authors raised two possibilities to explain these findings: DON metabolism in the jejunal epithelia or its accumulation in the tissues.

Conversely, AWAD et al. (2007) mounted chicken jejunum on UC and evaluated the flux rate of DON from the mucosal to the serosal side at 30, 60, 90 and 120 min. There was 6.3% passage at 120 min, which is higher than that registered herein. A review of the relevant literature did not disclose any results about AFB<sub>1</sub> passage through intestinal explants of birds using UC.

With respect to the removal of the seromuscular layer of the intestine described here, stripping was highly detrimental; the villi and the tissue structure were damaged, so the explant could not be used in the UC. Such data are in agreement with those reported when evaluating the viability of employing the UC to determine jejunal permeability of highly permeable compounds in several species; tissues were histologically analyzed before and after using the apparatus (NEIRINCKX et al., 2010).

Dissection of the jejunal seromuscular layer of turkeys, dogs, pigs and horses indicated the intestines of the two first species as inadequate for permeability evaluations. Moreover, attempts to remove the jejunal tissue of birds failed due to mucosal damage. The authors stated that intense epithelial damage and accumulation of mucus and cellular debris in the lumen are accountable for the low and greatly variable permeability across the jejunum of turkeys and dogs; the intestine of the pigs, in turn, was highly permeable. The findings observed in birds were attributed to the longer villi, the existence of wider and more numerous tight junctions facilitating paracellular transport, and the greater concentration and secretion rate of bile salt in this species.

Despite being scarce, literature reports indicate a low rate of mycotoxins passage through intestinal explants of birds (HALAWA et al., 2013) as well as a low tissue viability after stripping (NEIRINCKX et al., 2010), thus leading to unreliable outcomes. In view of that, the present investigation measured the amount of mycotoxin absorbed by the entire structure of the intestinal epithelium with all its layers intact.

As to efficacy tests, AMAs had a high percentage of adsorption *in vitro* and prevented absorption of the toxin. Nonetheless, the fact that

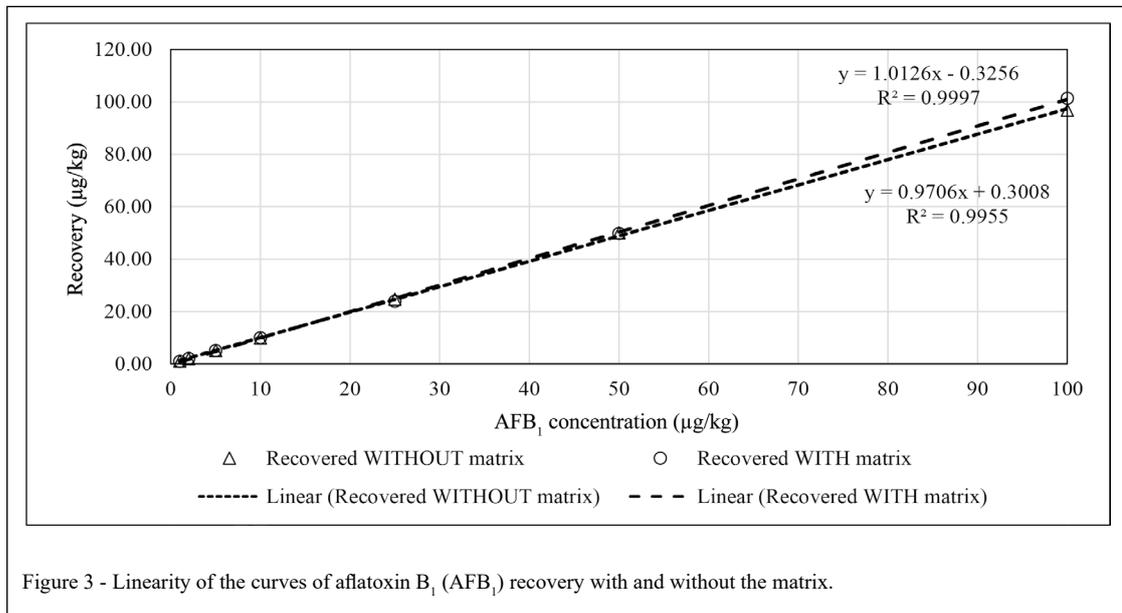

Figure 3 - Linearity of the curves of aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) recovery with and without the matrix.

they did not demonstrate the same percentage of adsorption when tested *ex vivo* must be highlighted, indicating that AFB<sub>1</sub> presented a greater affinity for the epithelium than for the AMAs. All AMAs showed an *in vitro* adsorption over 99%, while reduction in intestinal absorption of AFB<sub>1</sub> ranged from 67.11% to 86.28%; this may explain the differences commonly observed between *in vitro* and *in vivo* results: products which have an excellent *in vitro* efficacy show little or no efficacy *in vivo*. So, when included in animal feed, the AMA does not have the same potential to reduce the concentration of the toxin as it does *in vitro*, demonstrating that interaction of the toxin with the epithelium is more complex than the *in vitro* simulation of the intestinal juice.

The European Food Safety Authority (EFSA, 2010) reinforces these data: *in vitro* assays are considered a viable tool to analyze the potential of AMAs to act in mycotoxin control and may be used to provide information about their mechanism of action. Nevertheless, it mentions that such tests do not fully represent the conditions of the GIT and the differences between the target-animals and their metabolism and, consequently, must not be employed to demonstrate the efficacy of an AMA under natural conditions.

An *in vitro* model simulating the swine GIT was firstly used to evaluate the potential of activated carbon and cholestyramine to adsorb ZEN (AVANTAGGIATO et al., 2003). The method consists of four successive compartments simulating the stomach, duodenum, jejunum and ileum. The potential of several AMAs to adsorb or inactivate

mycotoxins was demonstrated by using simulations of the gastric, biliary and pancreatic secretions as well as bicarbonate to control the compartmental pH (AVANTAGGIATO et al., 2003, 2004, 2007).

The explants technique has recently been improved. ZHANG et al. (2017) mounted ileal fragments of broilers which had been damaged by *Clostridium perfringens in vivo* on UC and found a protective effect of dietary L-arginine upon the intestinal barrier. Another assessment used jejunal explants of piglets and showed *Lactobacillus rhamnosus* RC007 to be a promising AMA due to its ability to reduce DON toxicity (GARCIA et al., 2018). The same methodology was applied to evaluate DON's effect on intestinal explants of swine, and the ability of low doses of a chito-oligosaccharide to lessen the toxin's effects (GEREZ et al., 2018); the product was not able to avoid DON-induced damage.

Different results have been achieved in *in vitro* and *ex vivo* models applied to evaluate the adsorbent effect of a blend of probiotics (*Lactobacillus* and *Propionibacterium*) on AFB<sub>1</sub> in broilers (GRATZ et al., 2005). The adsorption potential obtained *in vitro* ranged from 57% to 66%, while in the *ex vivo* assay it was 25%; nonetheless, the *ex vivo* technique referred to animals' anaesthesia, ligation of a jejunal segment and injection of the toxin and probiotics. Another research evaluated the effects of DON upon intestinal morphology and activation of the mitogen activated protein kinases (MAPK) through *in vivo* and *ex vivo* models (LUCIOLI et al., 2013); results indicated the latter approach as a valuable tool to

assess gastrointestinal toxicity after exposure to low doses of toxins.

This is the first report on the use of UC to evaluate AMAs' efficacy employing intestinal explants of broilers. This *ex vivo* model proved valuable in the assessment of AMAs, and further studies are required to establish the correlation between the present technique and *in vivo* studies.

## ACKNOWLEDGEMENTS
