ASBTRACT: Projects are by their very nature subject to conditions of uncertainty that obstruct the decision-making process. Uncertainties involving forestry projects are even greater, as they are combined with time of return on capital invested, being medium to long term. For successful forest planning, it is necessary to quantify uncertainties by converting them into risks. The decision on whether to adopt replacement regeneration or coppice regeneration in a forest stand is influenced by several factors, which include land availability for new forest crops, changes in project end use, oscillations in demand and technological advancement. This study analyzed the economic feasibility of replacement regeneration and coppice regeneration of eucalyptus stands, under deterministic and under risk conditions. Information was gathered about costs and revenues for charcoal production in order to structure the cash flow used in the economic analysis, adopting the Net Present Value method (VPL). Risk assessment was based on simulations running the Monte Carlo method. Results led to the following conclusions: replacement regeneration is economically viable, even if the future stand has the same productivity as the original stand; coppice regeneration is an economically viable option even if productivity is a mere 70% of the original stand (high-tree planted stand), the best risk-return ratio option is restocking the stand (replacement regeneration) by one that is 20% more productive; the probabilistic analysis running the Monte Carlo method revealed that invariably there is economic viability for the various replacement and coppice regeneration options being studied, minimizing uncertainties and consequently increasing confidence in decision-making.

Key words: Forest economics, investment analysis, risk and uncertainty.

ANÁLISE ECONÔMICA DA REFORMA E DA TALHADIA DE POVOAMENTOS DE EUCALIPTO EM CONDIÇÕES DE RISCO

RESUMO: *Projetos estão sujeitos a condições de incerteza, que dificultam o processo de tomada de decisão. As incertezas nos projetos florestais são ainda maiores, pois estão aliadas ao tempo de retorno do capital investido, sendo de médio a longo prazo. Para o sucesso do planejamento florestal, é preciso quantificar as incertezas, convertendo-as em riscos. A decisão de reformar ou de conduzir o povoamento florestal é influenciada por diversos fatores, entre os quais se destacam a disponibilidade de terras para novos plantios, as alterações da finalidade do empreendimento, as variações na demanda e o avanço tecnológico. Nesse trabalho, analisou-se a viabilidade econômica da reforma e da condução da brotação de povoamentos de eucalipto, em condições determinísticas e de risco. Foram utilizadas informações de custos e receitas da produção de carvão vegetal para construir o fluxo de caixa usado para a análise econômica, realizada pelo método do Valor Presente Líquido (VPL). A avaliação do risco foi feita com base em simulações realizadas pelo método de Monte Carlo. Concluiu-se que: a reforma é viável economicamente, mesmo que o novo povoamento a ser implantado tenha produtividade igual a do povoamento original; a talhadia é uma opção viável economicamente mesmo que a sua produtividade seja de apenas 70% da do povoamento original (ou alto fuste); a opção de melhor relação risco-retorno é a substituição (reforma) do povoamento por outro 20% mais produtivo; a análise probabilística, realizada pelo método de Monte Carlo, permitiu verificar que, nas diversas opções de reforma e talhadia estudadas, ocorrerá sempre viabilidade econômica, diminuindo as incertezas e, conseqüentemente, aumentando a segurança para a tomada de decisões.*

1 INTRODUCTION

The use of *Eucalyptus* species is very popular in Brazilian forest enterprises, and knowledge of the optimal harvest age and optimal stand regeneration season is key to ensuring project success (REZENDE et al., 2005). According to Rodrigues et al. (1999), these forest enterprises seek to maximize the return on capital invested, regardless of the management being adopted, whether replacement regeneration or coppice regeneration.

The decision on whether to adopt replacement regeneration or coppice regeneration of a forest stand is influenced by several factors which include land availability for new forest crops, changes in project end use, oscillations in demand and technological advancements.

In some cases, coppice regeneration might be the most profitable alternative, while in other cases replacement regeneration might be the answer, due to increased yield potential through genetic improvement. Use of genetic improvement allows selecting progenies and productivity gains. In studies about genetic gain for *Eucalyptus* clones in Minas Gerais state, Botrel et al. (2007) found 6.98% gains in density and 6.89% gains in dry matter. According to Volker et al. (1990), estimates of volume gain for *Eucalyptus globulus* in Tasmania are in the range of 7% to 17%. Borralho et al. (1992) found a 20% to 47% gain in dry matter, in a study about expected genetic gain for *Eucalyptus globulus* in Portugal. Rocha et al. (2006) found a 13% to 22% gain in diameter for *Eucalyptus urophylla* originated in Indonesia and planted in Minas Gerais. According to Trugilho et al. (2001), the greater the variability in the trait of interest among clones or progenies, the greater the estimated gains resulting from genetic improvement.

Conducting a viability analysis is the natural course of business in every venture, looking to find the best alternative for capital investment. Studies involving economic assessment of forest management regimes usually address optimal harvest or rotation age, optimal stand regeneration season, ideal number of stump sprouts to be left in each planting hole when coppicing, number of coppice operations and economic rotation of the stand (NOBRE; RODRIGUEZ, 2001).

That said, projects are nonetheless subject to uncertainties that obstruct the decision-making process. Uncertainties involving forestry projects are even greater because they are combined with time of return on capital

invested, being medium to long term. For successful forest planning, it is necessary to minimize uncertainties by converting them into risks.

Risk is the variability of returns associated with a given asset and risk acceptance is divided into three categories: indifference to risk, aversion to risk and preference for risk (GITMAN, 2002). It is thus related to the creation of scenarios and simulation of factors influencing project viability, providing input to help decision-making.

Traditional methods of uncertainty assessment in the forestry sector typically resort to sensitivity analysis, which is used where information available about each variable is scarce or nonexistent. This analysis only assesses the impact of one independent variable at a time. However, when more than one variable influencing the decision-making process are analyzed, it is necessary to try all possible combinations between them, which makes this analysis more complex.

The Monte Carlo method is a robust analysis method known to be a powerful and useful tool, as it involves a set of random variables inherent in the project, in order to verify existing risk prior to decision-making. This methodology analyzes the *distribution of relevant variables*, as captured by a given probabilistic representation (COELHO JUNIOR et al., 2008).

The objective of this study is to analyze the economic viability of replacement regeneration and coppice regeneration of eucalyptus stands, under deterministic and risk conditions.

2 MATERIAL AND METHODS

2.1 Development of the economic model

Table 1 provides most likely costs for establishing eucalyptus stands, according to forestry companies in northern Minas Gerais state engaged in timber production for energy purposes. Costs are divided into: implementation, maintenance, harvest, transportation, carbonization, replacement regeneration, coppice regeneration and cost of land.

Cost of implementation comprised semiautomated and automated operations. Automated operations included land clearing (22.47%), soil preparation (15.65%), soil conservation (6.44%), fertilization (9.55%) and competitive weed control (4.18%). Semi automated operations included seedling planting (29.23%) and irrigation (9.01%).

For the situation of coppice regeneration, the following costs and revenues were adopted: C_0 is cost of implementation, C_1 , C_2 , C_3 and C_4 are costs of maintenance, C_5 is cost of land, C_6 and C_{11} are costs of harvest, C_7 and C_{12} are costs of carbonization, C_8 and C_{13} are costs of transportation, C_{10} is cost of coppice regeneration, while R_1 and R_2 are revenues from timber sales in year 7 and 14 respectively.

To enable a comparison of the two situations, a 14-year planning horizon was considered, which is the time required for one replacement regeneration and one coppice regeneration (Figure 1).

Revenue was based on the per ton price of dry matter (Pms), calculated on the basis of per cubic meter price of charcoal (mdc), in such way as to allow changes in basic density (Db), due to genetic improvement or coppice regeneration (WHITTOCK et al.; 2004). The equation used for the calculation is given as follows:

$$Pms = \frac{\frac{1}{Fc} * Pc}{Db}$$

where Fc is the conversion factor from m^3 of timber to m^3 of charcoal and Pc is the price per m^3 of charcoal.

Matthews (1992) and Underdown and Bush (2002) argue that, as a result of an established root system, volume yield from coppice regeneration can be up to 25% higher than that of the high-tree planted stand.

Loss from mortality, on the other hand, and/or postharvest damage to stumps, can dramatically reduce yield in the coppice method in comparison to the high-tree planted stand (FARIA et al. 2002; MATTHEWS, 1992).

Yield of the stand adopting replacement regeneration, and yield of the stand adopting coppice regeneration, were calculated as follows:

$$Pr_{melhorado} = Pr \left(1 + \left(\frac{gg}{100} \right) * \left(\frac{gv}{100} \right) \right)$$

$$Pr_{talhadia} = Pr * \frac{\%Pr}{100}$$

where: $Pr_{melhorado}$ is yield of the stand adopting replacement regeneration, Pr is yield of the original stand, gg is percentage of genetic gain, gv is percentage of genetic gain relative to volume gain, $Pr_{talhadia}$ is yield of the stand adopting coppice regeneration and $\%Pr$ is variation in yield of coppice regeneration relative to yield of original stand.

Genetic gain was divided in gain in volume and basic density, with 90% corresponding to gain in volume and 10% to gain in basic density. Scenarios were constructed, considering gains of 0%, 10%, 20%, 30%, 40% and 50% relative to original stand yield. In like manner, coppice yields of 70%, 80%, 90%, 100%, 110%, 120% and 130% were considered, relative to the original stand.

According to Albertsen et al. (2000), the cost of harvest in coppiced stands is higher than in original high-tree stands. To adjust this situation, cost of harvest for the coppiced stand was increased by 5% in relation to cost of harvest for the original stand. Table 2 provides a summary of additional information used in the economic assessment.

Table 2 – Data used in the economic assessment.

Tabela 2 – Dados utilizados na avaliação econômica.

Description	Unit	Value
Conversion factor	m^3/mdc	1.45
Sale price of charcoal (MG average)	R\$/ mdc	131.65
Sale price of dry matter	R\$/t	171.31
Discount rate	%	6
Yield of original stand	m^3/ha	300
Basic density	t/m^3	0.53
Drop in basic density using coppice method	%	5
Rise in cost of harvest using coppice method	%	5
% of total gain in volume	%	90
% of total gain in basic density	%	10

mdc^* = cubic meter of charcoal

2.2 Identification of input variables

Opportunities and threats influencing the yield in each management regime were identified, and input variables (*inputs*) included the yield of the high-tree planted stand, or original stand, and basic density.

A triangular distribution was used, the most likely value of basic density being 530 kg.m^{-3} for timber from the original stand (SCOLFORO et al., 2008). For timber from the coppiced stand, a 5% drop in basic density was assumed in relation to the original stand. For the stand subjected to replacement regeneration, it was assumed that timber density can be higher in the new clone, due to genetic improvement (SESBOU e NEPVEU, 1991).

As regards productivity, the most likely volume value for the high-tree planted stand was assumed as 300 m³/ha, while maximum and minimum values were assumed as 20% above and below that respectively.

2.3 Identification of the output variable

Both the deterministic analysis (risks are not taken into account) and the risk analysis adopted the Net Present Value (VPL) method as output variable, computed for an annual interest rate of 6%. According to Rezende e Oliveira (2008), VPL is given by the following equation:

$$VPL = \sum_{j=0}^n R_j (1+i)^{-j} - \sum_{j=0}^n C_j (1+i)^{-j}$$

where R_j is value of revenues; C_j is value of costs; i is interest rate; j is period in which revenues or costs occur; n is project duration.

2.4 Risk analysis

The risk analysis was conducted running the Monte Carlo method so as to simulate values for the input variables and, as a result of the random values generated, to obtain values for the output variable.

Cash flows were structured, and 10,000 simulations were run for the output variable using pseudorandom numbers, in other words, a series of values was generated for the variable and, consequently, its simple and cumulative frequency distribution was obtained.

3 RESULTS AND DISCUSSION

3.1 Deterministic economic analysis of management regimes

Table 3 provides VPL results according to deterministic analysis (risks are not taken into account), indicating that all tested alternatives are economically viable. In the situation of replacement regeneration it was noted that, with improved genetic gain, volume yield increases and so does VPL. Likewise, for different yields of the coppiced stand in relation to the original stand, as yield increases, so does expected return. Rezende et al. (2005) found the same VPL pattern relating to yield in studies of optimum cutting age for *Eucalyptus*.

In the harvest season, should there be a clone available capable of producing the same yield as the high-tree planted stand (zero genetic gain = G0), the VPL will be R\$ 3,696.39. Assuming the yield of the coppiced stand is the same as that of the high-tree planted stand (T100), the VPL will be R\$ 3,792.40, therefore coppice regeneration

Table 3 – VPL for different percentages of genetic gain in replacement regeneration and different yields of coppice regeneration in relation to the high-tree planted stand (original).

Tabela 3 – VPL para as diferentes porcentagens de ganho genético do povoamento reformado e as diferentes produtividades da talhadia em relação ao povoamento do alto fuste (ou original).

Situation	Code	Genetic gain	VPL
Replacement regeneration	G0	0%	3,696.39
	G10	10%	4,248.31
	G20	20%	4,821.91
	G30	30%	5,417.19
	G40	40%	6,034.16
	G50	50%	6,672.81
Yield of coppice stand			
Coppice regeneration	T70	70%	2,619.82
	T80	80%	3,010.68
	T90	90%	3,401.54
	T100	100%	3,792.40
	T110	110%	4,183.26
	T120	120%	4,574.12
	T130	130%	4,964.98

should be preferred over replacement regeneration. On the other hand, if the yield of the coppiced stand is only 90% of that produced by the original stand (T90), the VPL then drops to R\$ 3,401.54, in which case replacement is a better option than coppice regeneration.

Should there be a clone yielding 10% more than the high-tree planted stand (10% genetic gain = G10), then replacement should be more profitable than coppice regeneration, providing yield from coppicing is not more than 10% the yield of the high-tree planted stand (T110). For genetic gain of 30% (G30) or over, in no event should coppice regeneration be more viable economically than replacement regeneration.

This analysis is interesting for decision makers, as it provides return possibilities according to different management options prior to implementing them in the harvest season. For that, it is necessary to have prior information on expected yields of the coppiced stand and also on clones available for new crop planting.

Rocha et al. (2006) reported 13% to 22% gains in diameter for *Eucalyptus urophylla*. Botrel et al. (2007), in a study with *Eucalyptus* clones in Minas Gerais, found a 6.98% gain in basic density and a 6.89% gain

in dry matter. These results are strong indicators of the difficulty encountered today in attaining significant volume yield gains of wood or dry matter resulting from genetic improvement or from updated management and silvicultural techniques.

3.2 Economic analysis of management regimes under risk conditions

Results of Monte Carlo simulation for replacement regeneration and coppice regeneration are provided in Tables 4 and 5 respectively. No probability of negative VPL values occurring were noted in any of the simulations, in other words, there is no risk that the options being tested are economically inviable.

The values of standard deviation help confirm that risks of economic inviability are virtually nonexistent. In Table 4, for instance, for the no genetic gain (G0) situation, a standard deviation of R\$ 836.63 indicates that more than 5.6 standard deviations would be required for a zero

VPL. For the 50% genetic gain (G50) situation, risks of negative VPLs are even slighter, requiring for that a drop of 7.6 standard deviations in VPL.

As is illustrated in Table 5, for the situation where the yield of the coppiced stand equals that of the original stand (T100), the percentile analysis indicated a 10% probability of VPL having minimum values of R\$ 3,780.37 and a 90% probability of it having maximum values of R\$ 5,867.67.

Mode values are lower than median values and these in turn are lower than mean values, indicating that the probability distribution of VPL values is approximately normal with positive skewness.

Figure 2 provides several genetic gain situations for the high-tree planted stand, and yields from coppicing relative to the original planted stand. The analysis considered the point at which the cumulative distribution function intersects the theoretical curve of frequency distribution. VPL occurrence probabilities were noted to range between 70% and 85% according to each different situation.

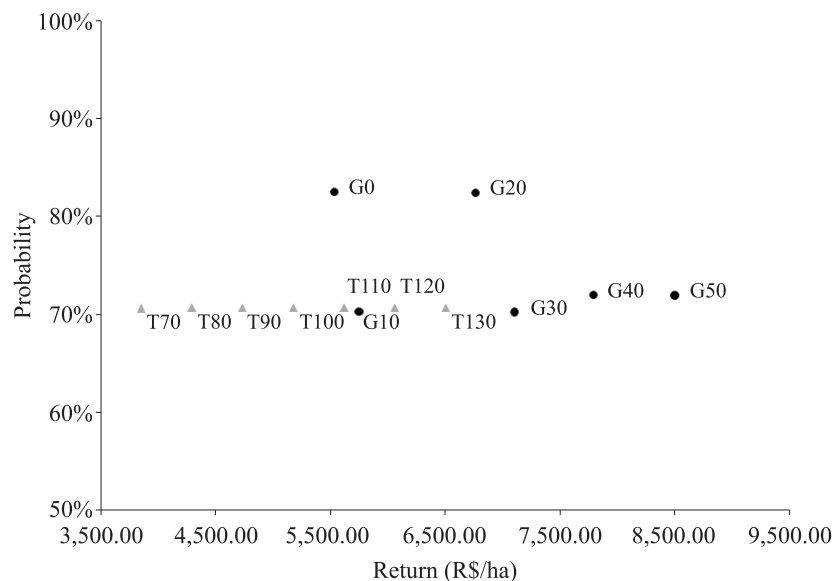

Table 4 – Descriptive statistics of VPL (R\$/ha), considering different percentages of genetic gain of the high-tree planted stand.

Tabela 4 – Estatísticas descritivas do VPL (R\$/ha), considerando as diferentes porcentagens de ganho genético do povoamento do alto fuste.

**Figure 2** – Probability of success and return (VPL) in R\$/ha for various management regimes.**Figura 2** – Probabilidade de sucesso e retorno (VPL) em R\$/ha para os diferentes regimes de manejo avaliados.

The option providing the best risk-return combination is the 20% genetic gain situation (G20), as it combines a high probability of return occurrence (82.52%) with a high return (VPL = R\$ 6,765.36). It should be noted, however, that attaining a 20% genetic gain with eucalyptus stands at present is a difficult task, due to the current technological stage of Brazilian silviculture.

The no genetic gain (G0) situation provides the second best risk-return combination. Here, the risk is lower (probability of return occurrence = 82.61%) than in G20, but then return too is lower (VPL = R\$ 5,532.09).

The no genetic gain (G0) situation is really what happens in practice with several forestry companies, since replacement regeneration uses the same clone as that of the original stand. Where the yield of the coppiced stand being 10% higher than the yield of the original stand (T110) is considered a plausible alternative, one should be aware of the risk of that not occurring in practice as a result of technology deficiency (operational risk).

In accepting the above risk, assuming that technology will enable yield from coppicing to be 10% higher than yield from the original stand (T110), coppice regeneration is a better option than replacement regeneration if there is no genetic gain (G0), that is, if the yield of the future stand equals that of the original stand. Considering that the yield of the coppiced stand equals that of the original stand (T100), the best option is replacement regeneration, if there is no genetic gain (G0).

4 CONCLUSIONS

Deterministic and risk analyses for the various options of replacement regeneration and coppice regeneration of Eucalyptus stands led to the following conclusions:

- replacement regeneration is economically viable, even if the yield of the new stand is the same as that of the original stand;

- coppice regeneration is economically viable, even if the yield is only 70% of the original stand (high-tree planted stand);

- the best risk-return ratio option is substituting (replacement regeneration) the original stand with another yielding 20% more;

- the probabilistic analysis running the Monte Carlo method revealed that invariably there is economic viability for the various replacement and coppice regeneration options being studied, minimizing uncertainties and consequently increasing confidence in decision-making.
