

Morphea after SARS-CoV2 vaccine[☆]

Dear Editor,

Along with the increasing administration of COVID-19 vaccines, in the last months, the detection of potential adverse skin reactions has increased, highlighting the possibility that not only SARS-CoV-2 infection but also COVID-19 vaccines can induce cutaneous manifestations.^{1,2} In this regard, type I hypersensitivity reactions (e.g., urticaria, angioedema and anaphylaxis) and type IV hypersensitivity reactions (e.g., inflammatory reactions in the site of injection, morbilliform and erythema multiforme-like rashes) are the most commonly observed; pityriasis rosea-like reactions, herpes zoster reactivations and functional angiopathies (e.g., chilblain-like lesions and erythromelalgia) have been also observed.² Contrariwise, there are very limited data regarding autoimmune skin diseases following SARS-CoV-2 vaccines² and there are only few reports of generalized morphea induced by COVID-19 mRNA vaccine.⁴

A 61-year-old Caucasian woman presented to our department with a 3-month history of ten, symmetrical, whitish, xerotic and sclerotic plaques, with a diameter ranging between 5 cm and 12 cm localized in the abdominal area, lower limbs, back and upper limbs (Figs. 1A-B and 2A). A dermoscopy of one lesion showed prominent whitish fibrotic beams (Fig. 2A). Her familiar and personal history was negative for autoimmune and chronic inflammatory skin disorders. She did never suffer from the Raynaud phenomenon, and she did not present sclerodactyly, with no facial involvement and no nail folds involvement. The patient referred

that the first lesions appeared in the abdominal area 15 days after the first dose of Comirnaty-Pfizer® SARS-CoV-2 vaccine and lesions grew in number and size 15 days after the second dose of the vaccine. The cutaneous lesions first arose as erythematous and itchy plaques, becoming subsequently whitish and sclerotic. A cutaneous biopsy of one lesion on the abdomen was performed. The histology showed thickening and hyalinization of connective tissue of the deep dermis and subcutaneous fat, with atrophy of adnexal structures, increased fibroblasts, and dense collagens through the deep dermis (Fig. 2B). Laboratory investigations showed the presence of antinuclear antibodies (1:160 in homogeneous pattern), presence of antibodies anti-receptor-binding domain SARS-CoV-2 at 113 U/mL (normal values: <80 U/mL), while antibodies to extractable nuclear antigens were negative. According to the clinical and histological correlation, a final diagnosis of Generalized Morphea (GM) was performed and a therapy with clobetasol propionate 0.05% cream was started in association with a systemic treatment consisting in methotrexate 7.5 mg per week, with a single dose of 5 mg of folic acid once per week. GM is identified by more than four plaques, at least 3 cm, that involves two or more anatomical regions and differs from scleroderma by the absence of Raynaud phenomenon, sclerodactyly, facial involvement, nail fold involvement, and specific autoantibodies.³ In this case, the onset of GM may be justified by the fact that vaccines can occasionally cause a new onset of flare of autoimmune-mediated diseases. Indeed, the spike protein of the SARS-CoV-2 vaccine shares genetic similarities with human proteins, being an important factor that can trigger autoimmune diseases after vaccination due to molecular mimicry and generation

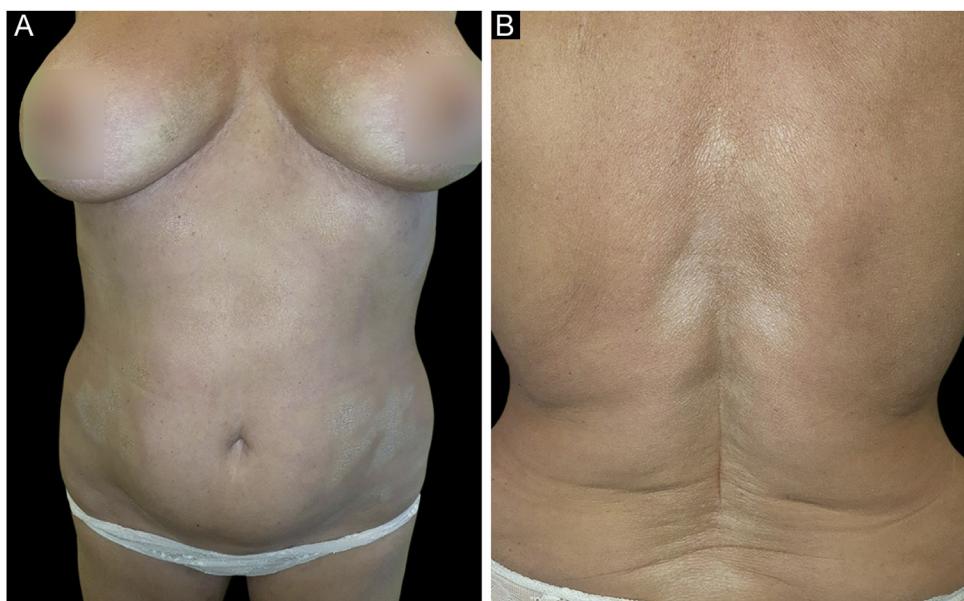

Figure 1 (A) Symmetrical, whitish, ivory, xerotic and sclerotic plaques, with a diameter ≥ 3 cm. (B) Whitish and sclerotic skin plaque with a "cigarette-paper" appearance on the patient's back.

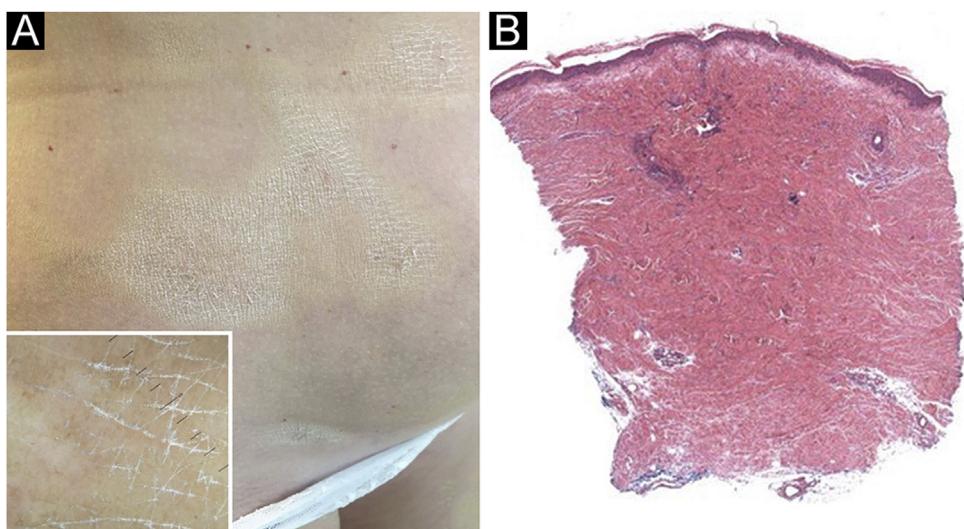

Figure 2 (A) Whitish and sclerotic plaques localized in abdomen and groin. Insert left: dermoscopy showed prominent whitish fibrotic beams and loss of hair in the involved area. (B) Histology showed a thickening and hyalinization of connective tissue of deep dermis and subcutaneous fat, with atrophy of adnexal structures, increased fibroblasts and dense collagens through the deep dermis (Hematoxylin & eosin, 50×).

of autoreactive lymphocytes.² At the same time, although the onset of cutaneous diseases after COVID-19 vaccines can highlight a causality association, the very large number of cases receiving SARS-CoV-2 vaccines during the last months may induce biases,² associating with vaccines also cutaneous manifestations that could have occurred independently. In conclusion, this is one of the few cases of GM arising after the SARS-CoV-2 vaccine and further cases are needed to better investigate a possible association of GM with this vaccination. Reporting potential side effects of COVID-19 vaccines is important for daily clinical practice; at the same time, to date, COVID-19 vaccines maintain a high safety profile, and accordingly, the population should not be discouraged from vaccinating.

Case for diagnosis. Multiple infiltrated plaques in a patient with human immunodeficiency virus and hepatitis C co-infection: lichen myxedematosus[☆]

Dear Editor,

This report describes the case of a 45-year-old male patient, smoker, diagnosed with human immunodeficiency virus (HIV) and hepatitis C virus (HCV) infection three years before. He was undergoing regular treatment with antiretroviral therapy (ritonavir, tenofovir and atazanavir), and had an undetectable viral load, with a CD4 cell count of 534 cells/mm³, but without treatment for hepatitis C. He complained of cutaneous lesions with two years of evolution, and significant worsening in the last months, with local pruritus. On examination, erythematous, infiltrated papules and plaques were observed in the gluteal region bilaterally, as well as in the left abdominal, cervical and upper dorsal regions (Figs. 1–3). He underwent laboratory tests that showed AST (aspartate aminotransferase) of 82 U/L, ALT (alanine aminotransferase) of 115 U/L, GGT (gamma-glutamyl transferase) of 131 U/L, alkaline phosphatase of 83 U/L, total bilirubin of 1.28 mg/dL, and fasting glucose of 103 mg/dL. Other laboratory tests within normal limits included: Hb, 15.3 g/dL; leukocytes,

Figure 1 Erythematous, confluent plaques with an infiltrated appearance, in the gluteal region, bilaterally.

5800 mm³; platelets, 205,000 mm³; TSH, 2.51 IU/mL; free T4 1.08 µg/dL; Cr 0.79 mg/dL; non-reactive ANA (antinuclear antibody), non-reactive rheumatoid factor, proteinogram with no monoclonal peaks. A skin biopsy was performed, which showed abundant mucin deposits in the upper and middle dermis (Fig. 4).

Figure 2 Erythematous plaque with a papular center on the left abdominal region.

Figure 3 Erythematous, whitish papules on the upper back and posterior cervical regions.

What's your diagnosis?

- a) Lichen amyloidosus;
- b) Lichen myxedematosus;
