

Usefulness of 3'- 5' IS6110-RFLP genotyping and spoligotyping of *Mycobacterium tuberculosis* isolated in a tertiary hospital: a retrospective study detecting unsuspected epidemiological events

Silvia Maria de Almeida¹, Ana Carolina Malaspina², Clarisse Queico Fujimura Leite², Maria Helena Féres Saad¹

ABSTRACT

A drug resistance survey involving *Mycobacterium tuberculosis* isolated from patients of a tertiary Hospital in the Rio de Janeiro city (RJ), Brazil, between the years 1996 and 1998 revealed a high frequency of isoniazid (H^R) resistance. These isolates were revisited and genotyped. Patients came from different RJ neighborhoods and municipalities, and 70% were outpatients. Applying the 3' and 5' IS6110-RFLP and the Spoligotype genotyping methods, the clonal structure of this population was investigated obtaining a snapshot of past epidemiological events. The 3' clusters were subsequently 5' IS6110-RFLP typed. Spoligotyping was analyzed in the SITVIT2 database. Epidemiological relationships were investigated. The major lineage was T (54.4%), and SIT 53/T1 and SIT 535/T1 were the most frequent. The T1 sublineage comprises 12.8% of resistant strains and SIT 535 were assigned for 31.8% of them. Orphan patterns corresponded to 12% and 73.3% and belonged to the T lineage. One pattern was unlisted in the SITVIT2. The 5' IS6110-RFLP did not confirm 3/12 of the 3' IS6110-RFLP clusters. A combination of all methods decreased the number of clusters to three. Nosocomial transmission was associated with one cluster involving a hospital cupbearer. This event was suspected in a multidrug resistant-TB inpatient caregiver who harbored a mixed infection. The 3' IS6110 clusters were associated with H^R (p=0.046). These genotypic retrospective data may reflect a fraction of more extensive recent transmission in different communities that may be corroborated by the concentration of H^R patients, and may serve as a database for further evolutionary and characterization evaluation of circulating strains and together with epidemiological data favors a more effective transmission control.

KEYWORDS: Tuberculosis. *Mycobacterium tuberculosis*. 3'-5' IS 6110 RFLP. Mixed infection. Nosocomial transmission.

INTRODUCTION

Tuberculosis (TB) is an airborne-transmitted disease with an estimated 10.0 million (range, 9.0–11.1 million) new cases worldwide and 1.3 million deaths occurring in 2017. Brazil, with 91,000 notifications, ranks 19th among 30 high-burden countries and contributes with 33% of the total cases in the Americas^{1,2}. Currently, the Rio de Janeiro State, with high population density rates ($\approx 5,265.82$ inhabitants/km²), presents a TB incidence of 63.5/100.000 inhabitants (inh). Regrettably, this is higher in the Rio de Janeiro city (RJ) (85.5/100.000 inh.), ranking second in the country, presenting the highest death rate (4.4/100.000 inh.)^{3,4}. However, in 1995, this State was ranked in the same position, with a high percentage

of TB retreatment⁵ and with one-third of TB cases being reported in hospitals⁶. A survey carried out from 1996 to 1998 at the Pedro Ernesto University Hospital (HUPE), which, as a tertiary health service received patients from different geographic areas of RJ, indicated an isoniazid-resistant *M. tuberculosis* rate of 13%⁵.

Genotyping methods, such as spoligotyping and RFLP, are performed to understand TB transmission. These routine approaches are used in several developed countries, while molecular studies are punctual in developing countries and usually only one genotyping method is used. Spoligotyping is less powerful for cluster investigations than IS6110-RFLP. Nevertheless, if strains are isolated from patients coming from different geographic areas, cluster definition failures may occur, as the restriction sites may be located in different points throughout the IS6110 sequence on the bacterial genome. This is due to genetic mechanisms that can lead to loss of the restriction site flanking the IS6110 insertion, compromising case grouping. An alternative method that increases the probability of grouped strains actually being related clones, especially if strains are isolated from unrelated geographic areas, has been described using the 5' IS6110 probe⁷. Briefly, the physical IS 6110 map indicates a single *Pvu II* restriction site that has been successfully applied to the cleavage of these sequences in order to obtain two IS 6110 restriction fragments of different sizes, reflecting polymorphisms between strains. The right side of the *Pvu II* restriction site was arbitrarily chosen for the standardization of RFLP genotyping by reducing the number of IS6110 fragments to the half. In some cases, for a better differentiation between strain patterns, membranes could be re-hybridized with labeled DNA probes containing only of the IS6110 fragment on the left of the *Pvu II* restriction site⁸ (Figure 1). On the other hand, the RFLP-IS6110, despite being more laborious than the MIRU-VNTR, a PCR based method using 12 or 24 interspaced markers, or spoligotyping, requiring higher amounts of DNA, has the advantage of a strong genetic stability, which makes this technique appropriate to identify true clusters in old population strains⁹.

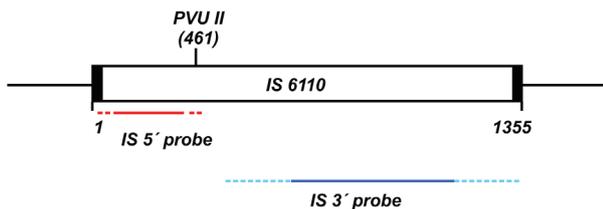

Figure 1 - Schematic representation of the 6110 insertion sequence (IS), present in the *Mycobacterium tuberculosis* genome, cleaved by the *Pvu II* endonuclease yielding two fragments⁸ used as probes in restriction fragment length polymorphism 3' IS6110 and 5' IS6110 genotyping studies.

In the present study, taking the advantage of data availability and isolates from HUPE patients, a retrospective cluster investigation by 3' - 5' IS6110- RFLP is reported, using the same membrane and the spoligotyping scenario on phylogenetic diversity. Clusters defined by all methods and the investigated epidemiological relationships provided a snapshot of past epidemiological events.

MATERIAL AND METHODS

Study site, patients and *M. tuberculosis* isolates

Despite its location in the Vila Isabel neighborhood, in the Rio de Janeiro city, HUPE receives patients from several other municipalities, as well as other States, since it is a referral center for AIDS treatment, as well as for many primary and secondary health care units. From August 1996 to February 1998, the hospital had 604 beds and presented an estimated 350 TB cases diagnosed per year. However, the hospital presented no respiratory isolation beds and no TB control actions⁵. A total of 415 isolates from 248 patients identified in the previous study, were subcultured in Löwenstein Jensen's medium (LJ) and 125 growths (30.1%) from 106 (43%) patients from different neighborhoods and municipalities in Rio de Janeiro were obtained. Multiple isolates (36/125) were obtained from 17 patients (Figure 2). Most of these patients harbored two isolates, except for two, which presented three isolates each. Of the total number of isolates, 70% belonged to outpatients, while the remaining patients spent an average of 14.6 ± 13.1 days in the hospital. Most individuals sought HUPE care with suspected pulmonary TB (83%).

Previously, biochemical tests, (positive niacin production, positive nitrate reductase activity and negative catalase thermal-inactivation), identified the *M. tuberculosis* complex (MTBC), while drug susceptibility testing (DST) to isoniazide (H), rifampicin (R), pyrazinamide (Z), streptomycin (S), ethambutol (Eb) and ethionamide (Et) was performed by the standard proportion method in LJ medium, at the Central Noel Nutels Laboratory (LACENN), RJ¹⁰. Socio-demographic, clinical and laboratory data analyses were carried out by assessing the patients' medical records. No contact or personal interviews were performed with patients to obtain additional information. This study was approved by the HUPE Research Ethics Committee.

Molecular typing

CTAB-DNA based extraction was performed¹¹ in 113 isolates from 95 patients, while thermolysis extraction was carried out for the remaining isolates¹². Spoligotyping

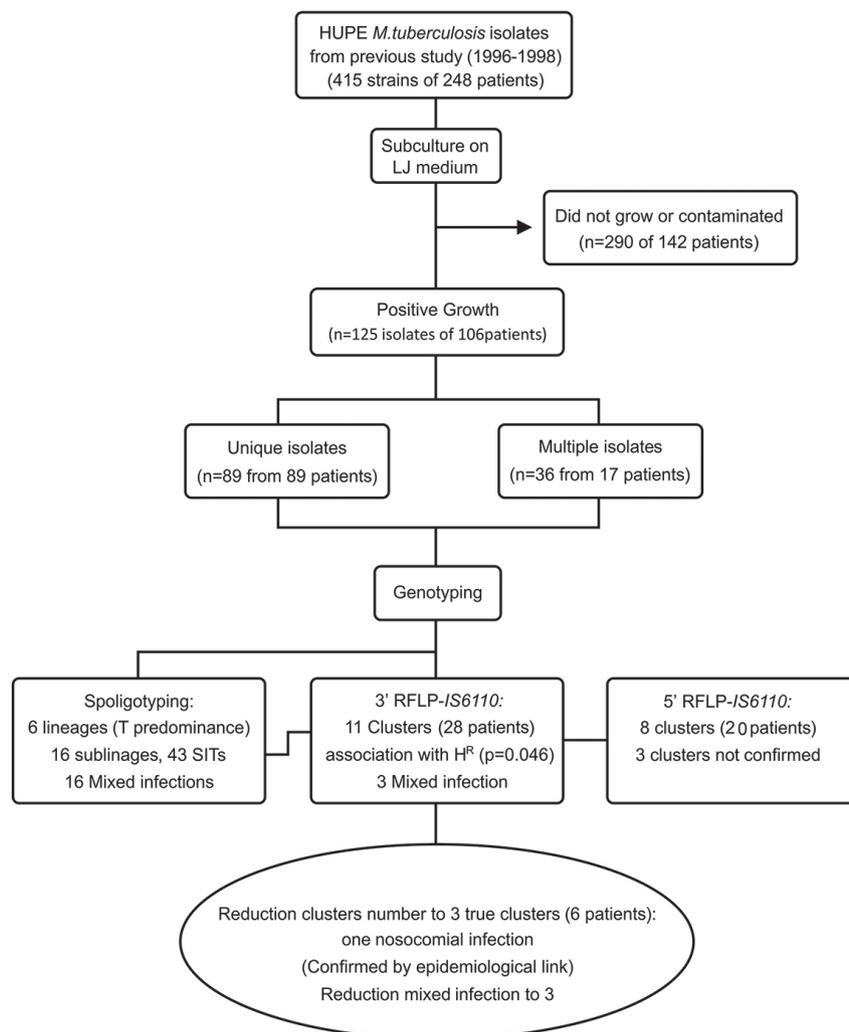

Figure 2 - Flowchart on the recovery of *M. tuberculosis* isolates of TB patients attended at the tertiary Pedro Ernesto University Hospital, Rio de Janeiro, Brazil, 1996-1998, and the main genotyping results.

follow the Kamerbeek *et al.*¹³ protocol, using spoligo-membranes from Ocimum Biosolutions Ltda (Hyderabad, India). An overestimation of the number of potentially related isolates is a possibility, as the discriminatory power of spoligotyping is lower and patients were from unrelated communities. Thus, 3' *IS6110*-RFLP-based typing was applied. The clusters obtained by this method were also 5' *IS6110*-RFLP typed. The 3' *IS6110*-RFLP technique was carried out as previously described^{8,14}. The 5' *IS6110*-RFLP method was performed as described elsewhere^{15,16}, with minor modifications. Briefly, probe hybridization was carried out on the same 3' *IS6110* assayed membranes after removal of the precipitated blue color and the 3' probe by heating the membranes at 50-60 °C in pure dimethylformamide (Dig nucleic acid detection kit, Roche, USA). The positive and negative controls for each experiment were the ATCC 14323 *M. tuberculosis* and an *M. avium* clinical isolate, respectively. Laboratory

cross-contamination was ruled out through verification that isolates with an identical fingerprint pattern had not been processed on the same day. To avoid risks of cross-contamination during cultivation and preparation of clinical samples for genotyping, all sample processing took place in laminar flow cabinets and only a limited number of specimens were processed on the same day.

Data analyses

Spoligotyping patterns were documented as octal and binary codes and compared to the SITVIT2 proprietary database¹⁷ an updated version of the SITVITWEB database¹⁸. The Spoligotype International Type (SIT) classification designates identical patterns shared with at least one other profile present in the database, while "orphan" patterns are applied for a single isolate that does not present any homology among patterns recorded in the

repository database. New spoligo patterns, whether orphan or encountered in multiple isolates in the present population, were repeated. Phylogenetic lineage identification was according to the signature provided by the database, defining 62 genetic lineages/sublineages. Georeferenced data allowed the identification of the geographic location of the spoligopatterns, as well as of true-clustered patients, through the home address of each patient (Figure 3). Spoligotypes

and 3' and 5' IS6110-RFLP patterns were analyzed by the Bionumerics 5.3 (Applied Maths, NV, Sint-Martens-Latem, Belgium) and/or GelCompar 3.1 (Applied Maths, Kortrijk, Belgium) softwares and supplemented visually. Cluster definition was two or more patients infected with *M. tuberculosis* harboring the same genotype obtained by the spoligotyping and 3' IS6110 methods. However, true clusters were assigned to those with the same genotype patterns

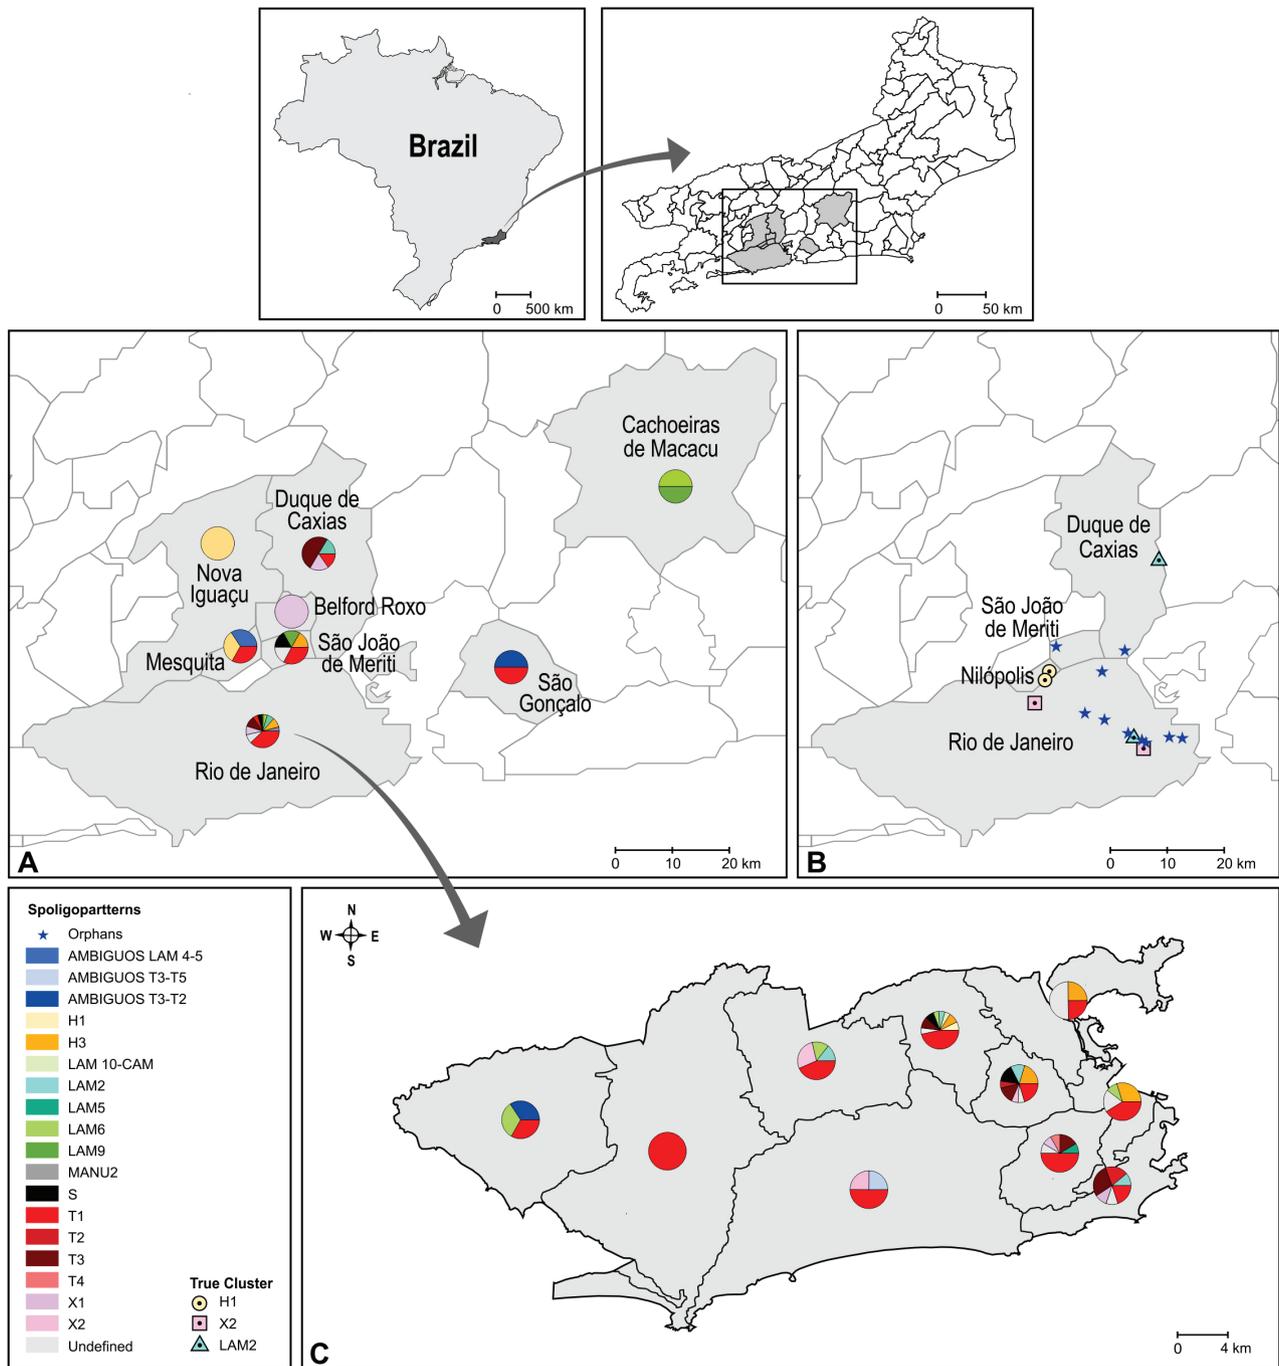

Figure 3 - Espatial georeferenced distribution of genotyped *M. tuberculosis* strains isolated from patients attended at the Pedro Ernesto University Hospital in Rio de Janeiro, Brazil, 1996-1998: A) Rio de Janeiro State; B) true clustered patients defined by 3' - 5' IS 6110-RFLP and spoligotype, and orphans spoligopatterns; C) Rio de Janeiro city.

combining all three methods, followed by epidemiological link assessments. Statistical significance between categorical variables was Chi-square estimated by Yates correction and an odds ratio at a 95% confidence interval, in order to establish associations among the clustered patients. The discriminatory power of 3' RFLP IS 6110 was calculated by applying the numeric discriminatory index (HGDI), as suggested by Hunter and Gaston¹⁹.

RESULTS

The spoligotyping method distributed the isolates into six lineages and 16 sub-lineages, as displayed in Figure 4. Most belonged to the ill-defined T spoligotype (68/125, 54.4 %), which predominates in different Rio de Janeiro

neighborhoods, including 73 % of the orphan SIT patterns. The H and LAM, X, S and Manu2 lineages were less frequent (≥ 12.8 %). Surprisingly, the usually low banding X clade presented two strains with higher copy numbers (> 10). One new spoligopattern signature (0.8%) was identified. Four new shared types resulting from this study were created in the database, SIT1906 (LAM6), SIT1907 (Ud), SIT1909 (T1) and SIT1911 (T3). Different SITs (n=43) and 88/125 (70.4%) isolates belonged to 23 groups. The largest genetic group comprised 15 isolates of the ubiquitous SIT53 (17%), followed by 10 isolates presenting Asian or African spoligotype (11.4%), belonging to the T1 sub-lineage, which also predominated in six other genetic groups from two patients. It is noteworthy that most of drug-resistant isolates were from the T1 lineage

dying three months later (06/07/1997). The other patient, a HUPE cupbearer employee who also suffered multiple hospitalizations in different HUPE wards, presented a marked tuberculin skin test and positive AFB sputum smear, only 31 days (04/16/1997) after the TB diagnosis of the first patient. Patients underwent treatment with TB first line drugs and isolates were Et^R.

The other two clusters displayed no special epidemiological features and no associations could be established, as the patients lived in different neighborhoods far from each other (>39 km) (Table 3). No epidemiological relationships were found for the remained clusters defined by the 3' RFLP probe.

Concerning the possible mixed infection cases, a decrease to three was observed after combining the spoligotyping and the 3' IS6110-RFLP method (Table 1). MDR harboring an extra Et resistance were identified in one of the isolates. The linked patient was BCG scar positive and a TB HUPE inpatient caregiver. The two-sputum exam

collections were carried out one month apart, and treatment was initiated with RHZ after the patient has informed never having received treatment for TB. Although this patient may have been involved in a nosocomial transmission event, no reliable epidemiological relationship could be established, since the other patient harboring an isolate with the same clonal pattern developed TB 11 months afterwards, was fully drug sensitive and reported TB treatment 15 years prior to this event. The remaining two polyclonal cases were inpatients for at least nine days, living in different Rio de Janeiro neighborhoods. Both stated that they had never been treated for TB, BCG scars were present and sputum exams on different days/months indicated fully drug susceptible isolates (Table 1).

DISCUSSION

Retrospective studies focusing on genotyping pattern frequencies provide important data on the relationship

between risk factors and diseases. Scarce studies using spoligotype had been carried out at that time in Brazil so that little is known about the most frequent spoligopatterns. In addition, few studies using two or more genotyping methods to investigate clustered infected TB patients have been performed. In the present study, a greater diversity of spoligopatterns in the South, North and central zones of the city of Rio de Janeiro is noteworthy (Figure 3). The T lineage, one of the most prevalent genotypes in Africa, Central South and North America and Europe¹⁷, was the most frequent herein, corresponding to over one third (36.6%) of the T1 sublineage (Figure 4).

Currently, the ubiquitous LAM clade is the major circulating lineage in RJ, as described in a study carried out in 11 Brazilian States in which RJ contributed with 40% of all typed isolates, mainly obtained from hospitals (2000 to 2005), as well as with 65 % of the LAM family^{20,21}. In another study, the predominance of LAM (69.4 %) was observed when analyzing the *M. tuberculosis* structure population of TB patient prison inmates in the city of Rio de Janeiro (2005 to 2006), with the second largest cluster composed of LAM2/SIT179 isolates, and one H^r²². Increments in global LAM burdens may be associated to MDR and extensive MDR, thus indicating the molecular monitoring as an important tool to understand the distribution of the molecular structure of mycobacterial strains in this setting²². It is interesting to note that MDR belonging to the LAM2/SIT179 lineage in the present study was mainly drug resistant (Table 1), although 3' IS6110-RFLP patterns were

different from those of the prison study. This suggests the importance of combining genotyping methods in a high-TB burden area of a closed environment, such as a tertiary hospital or prison.

According to mathematical modeling studies, it is unlikely that drug-resistant isolates spread more easily than drug susceptible ones²³. In this retrospective study, although no epidemiological relationship was detected regarding H^r patients, the findings may imply that these cases may have resulted from recent transmission, possibly from the home environment and/or social network, including primary multidrug resistant strains, as only two of the patients infected with drug-resistant *M. tuberculosis* underwent previous treatment. Moreover, the data corroborate other studies suggesting that all-major circulating families are associated to resistance in a given geographic area^{24,25}. In a recent report concerning strains isolated from Veracruz, Southeastern Mexico, the T lineage was predominant and 8/10 samples of the T1 sublineage were SIT 53 multidrug-resistant²⁶. Similarly, 47% (27/58) of all drug resistant isolates detected in the present study belonged to the T superfamily, with T1 contributing to most cases (22/27, 78.6%). It is intriguing that, despite the prevalence of the ubiquitous SIT 53/T1 prototype, the evolutionary SIT 535, comprised 70% of drug resistant strains (7/10) through the loss of three DR spaces. To the best of our knowledge, SIT 535 is not frequent in Brazil or in RJ in recent years²⁰, although, as stated previously, genotyping studies are still scarce. Thus, this may suggest an endemic manner of transmission.

Another unusual genotype comprised high banding pattern X lineage strains. Unfortunately, the investigation of a mixed-clonal event in these patients was not possible,

as only one culture sample was available, and both isolates did not grow in subcultures. However, recently Gonzalo-Asensio *et al.*²⁷ have described a direct correlation between

the normalized expression of *IS6110* and the abundance of copies in MTBC chromosomes, including X lineage strains, varying from <5 to 14 copies. In this retrospective molecular analysis, although the gold standard 24 MIRU-VNTR method²⁸ was not applied, the 3' and 5' *IS6110*-RFLP methods defined clusters comprising isolates from different geographic areas and were able to disclose differences in the restriction fragment size pattern up to additional six fragments (Table 4). Furthermore, a partial lack of genotypic cluster similarity was detected by all methods, leading to decreased cluster frequency, indicating that the results may reflect fractions of a possible recent transmission from different communities. The significant ($p=0.046$) cluster associations with H^R may support this hypothesis.

Recently, a one-year genotyping of *M. tuberculosis* isolated from the city of Porto, Portugal, by using 24 MIRU, found no evident chain of transmission of one or a limited number of specific genotypes²⁹, a similar pattern to the HUPE strains observed herein, evidencing that multiple genotypes circulated in the urban area of Rio de Janeiro. Concerning the possible recent transmission episodes represented by HUPE clusters, no clear or classical epidemiological relationship could be established, as for the Porto study, suggesting a high genotypic structure diversity of *M. tuberculosis* circulating in the study area.

The present study presents certain limitations. Firstly, old samples and inadequate storage led to the unsuccessful subculture of many resistant strains. In addition, the 5' *IS6110*-RFLP method was performed only among strains clustered by 3' *IS6110*-RFLP. However, as proof of concept, this strategy was adequate. Finally, the study was carried out in a short timeframe, but this is justified by the fact that it is part of an earlier cross-sectional study. Despite this, and the fact that RFLP is more time-consuming and cumbersome than MIRU-VNTR, the RFLP method disclosed unsuspected and possibly transmitted infections aside from mixed infections, including for MDR strains. Immunodeficient and immunocompetent individuals may be infected with more than one strain during the same disease episode (mixed infection), or reinfected by a second *M. tuberculosis* strain during recurrent episodes (exogenous reinfection)³⁰. Huyen *et al.*³¹ reported 3.1% of mixed infections by combining RFLP and spoligotyping in a rural area of Vietnam, equal frequency of our study, using both methods. Another study carried out a retrospective genotyping in previously samples suspected of having epidemiological relationships³², which in contrary to the present study, they described a slightly more adequate RFLP cluster results compared to MIRU-VNTR^{32,33}. Additionally, RFLP lacks the discriminatory power for strains presenting less than six banding patterns, while

spoligotyping and MIRU-VNTR are more adequate in this regard. Herein, only 2/7 low banding strains were clustered by all applied genotypic methods, displaying the same drug resistance, suggesting a possible transmission, although no epidemiological relationship was detected (Tables 3 and 4). According to Jonsson *et al.*³², clustering is an important finding, but not a crucial evidence of true relationships.

In conclusion, despite being time-consuming, the 3' - 5' *IS6110*-RFLP and spoligotyping techniques revealed an association risk and unsuspected past epidemiological events. In fact, the success of this study relies on available epidemiological data information. This study may, therefore, serve as a database for further evolutionary and characterization evaluation of circulating strains and, along with epidemiological data, may aid in more effective transmission control measures, mainly in close settings.

AUTHORS' CONTRIBUTIONS

SMA: responsible for the implementation of the study in all phases of technical and experimental development as well as in the collection and statistical analysis of the data obtained and the preparation of the manuscript. ACM: collaborated in the analysis of the results of genotyping. CQFL: supervised the implementation of the genotyping methods and the analysis of the results of genotyping. MHFS: designed the study, supervised all stages of the implementation and study development, wrote and reviewed the manuscript. All authors contributed to the interpretation of the results and the revision of the manuscript.
